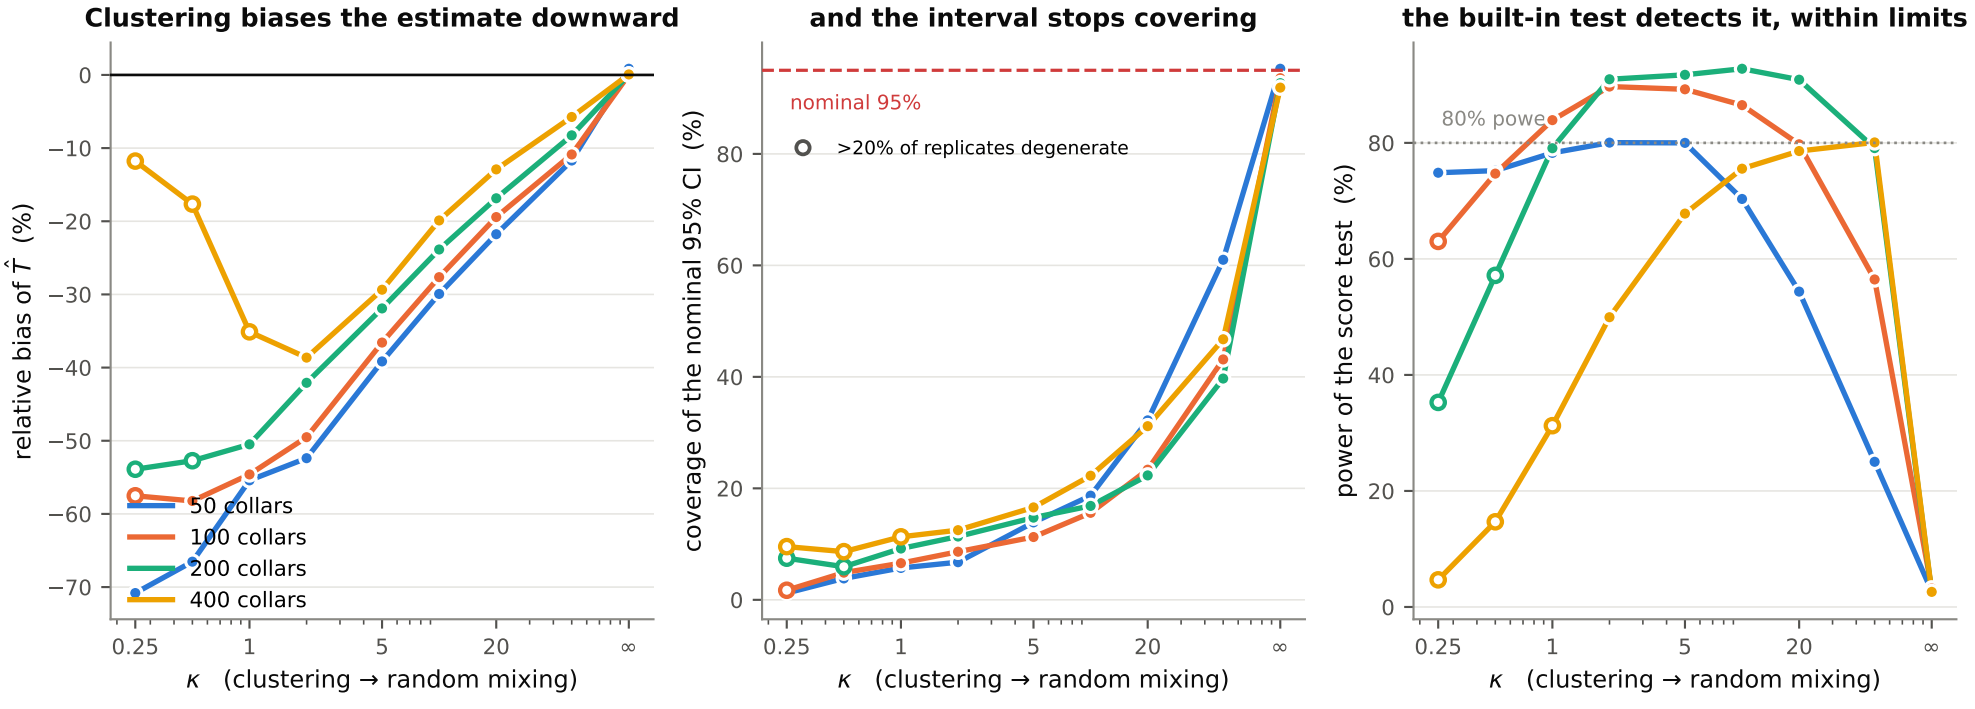
Departure from random mixing, not sampling error, is what breaks the estimator — and more collars do not fix it



1,000 replicates per cell. κ is the Dirichlet concentration of the collar allocation: $\kappa = \infty$ is exact random mixing, smaller values clump collars into fewer groups. The x axis is logarithmic in κ with ∞ placed at the right; hollow markers summarise only the replicates that converged, so the apparent recovery at the smallest κ is survivorship, not improvement.
